First draft: June 2004. This draft: July 2005.

Abstract

In the data, individual prices change frequently and by large amounts. In standard sticky price models, frequent and large price changes imply a fast response of the aggregate price level to nominal shocks. This paper presents a model in which price setting firms optimally decide what to observe, subject to a constraint on information flow. When idiosyncratic conditions are more variable or more important than aggregate conditions, firms pay more attention to idiosyncratic conditions than to aggregate conditions. When we calibrate the model to match the large average absolute size of price changes observed in the data, prices react fast and by large amounts to idiosyncratic shocks, but prices react only slowly and by small amounts to nominal shocks. Nominal shocks have persistent real effects. We use the model to investigate how the optimal allocation of attention and the dynamics of prices depend on the firms' environment.

JEL: E3, E5, D8.

Key words and phrases: rational inattention, sticky prices, real effects of nominal shocks.

“An optimizing trader will process those prices of most importance to his decision problem most frequently and carefully, those of less importance less so, and most prices not at all. Of the many sources of risk of importance to him, the business cycle and aggregate behavior generally is, for most agents, of no special importance, and there is no reason for traders to specialize their own information systems for diagnosing general movements correctly.” (Lucas, 1977, p. 21)

1 Introduction

In the data, individual prices change frequently and by large amounts. Bils and Klenow (2004) and Klenow and Kryvtsov (2004) study micro data on consumer prices that the U.S. Bureau of Labor Statistics collects to compute the consumer price index. Bils and Klenow find that half of all non-housing consumer prices last less than 4.3 months. Klenow and Kryvtsov find that, conditional on the occurrence of a price change, the average absolute size of the price change is over 13 percent.¹

At the same time, the aggregate price level responds slowly to monetary policy shocks. A variety of different schemes for identifying monetary policy shocks yield this result (e.g. Christiano, Eichenbaum and Evans (1999), Leeper, Sims and Zha (1996) and Uhlig (2005)). Uhlig (2005) finds that only about 25 percent of the long-run response of the U.S. GDP price deflator to a monetary policy shock occurs within the first year after the shock.

This combination of empirical observations is difficult to explain with standard models of sticky prices. The popular time-dependent model of price setting due to Calvo (1983) can explain a slow response of the aggregate price level to a monetary shock if: (a) firms in the model adjust prices infrequently;² or (b) firms in the model adjust prices by small

¹The finding that individual prices change frequently and by large amounts is robust to whether temporary price changes reflecting sales are included or not. When Bils and Klenow (2004) net out the impact of sales, the median price duration rises from 4.3 to 5.5 months. When Klenow and Kryvtsov (2004) net out the impact of sales, the average absolute size of price changes falls from 13.3 to 8.5 percent.

²Galí and Gertler (1999) estimate the Calvo model using quarterly aggregate U.S. data. The estimated model implies that a typical firm waits about 5-6 quarters before changing its price.

amounts.³ However, neither (a) nor (b) seems to be true in the data.

Golosov and Lucas (2005) conduct numerical experiments with a state-dependent model of price setting. They use the micro data on consumer prices compiled and described by Klenow and Kryvtsov (2004) to calibrate a menu cost model with monetary shocks and idiosyncratic productivity shocks. In the calibrated model, the aggregate price level responds quickly to a monetary shock. The reason is that a firm setting a new price in a menu cost model takes into account current values of all shocks. Hence, frequent price adjustment implies a fast response of prices to all shocks, including monetary shocks.

This paper presents a model that can explain why individual prices change frequently and by large amounts and, at the same time, the aggregate price level responds slowly to monetary policy shocks. We study price setting by firms under “rational inattention” in the sense of Sims (2003). Firms can change prices every period at no cost. The profit-maximizing price depends on the aggregate price level, real aggregate demand and an idiosyncratic state variable (reflecting consumers’ preferences or the firm’s technology). Firms decide what to observe. Firms choose the number of signals that they receive every period as well as the stochastic properties of these signals. Firms face the constraint that the information flow between the sequence of signals and the sequence of states of the economy is bounded. Other properties of the signals are up to the firms. In particular, since the state of the economy is multidimensional, firms decide which variables to observe with higher precision. We close the model by specifying exogenous stochastic processes for nominal aggregate demand and the idiosyncratic state variables.

The model makes the following predictions. Firms adjust prices every period and yet impulse responses of prices to shocks are sticky – dampened and delayed relative to the impulse responses under perfect information. The extent of dampening and delay in a particular impulse response depends on the amount of attention allocated to that type of shock. When idiosyncratic conditions are more variable or more important for the price setting decision than aggregate conditions, firms pay more attention to idiosyncratic conditions than to aggregate conditions. In this case, price reactions to idiosyncratic shocks are

³See Woodford (2003, Chapter 3) for reasons why firms can find it optimal to adjust prices by small amounts in response to shocks.

strong and quick whereas price reactions to aggregate shocks are dampened and delayed. This can explain why individual prices change frequently and by large amounts and, at the same time, the aggregate price level responds slowly to nominal shocks. In addition, there is a feedback effect. When firms pay little attention to aggregate conditions, the aggregate price level moves little and therefore firms find it optimal to pay even less attention to aggregate conditions. This feedback effect makes the response of the aggregate price level to a nominal shock even more sticky.

We calibrate the model to match the average absolute size of price changes reported in Klenow and Kryvtsov (2004). We find that prices react fast and by large amounts to idiosyncratic shocks, but prices react only slowly and by small amounts to nominal shocks. Nominal shocks have persistent real effects. The reason is the following. To match the large average absolute size of price changes observed in the data, idiosyncratic shocks in the model must have a large variance or must be very important for the price setting decision. This implies that firms allocate most of their attention to idiosyncratic conditions.

We use the model to investigate how the optimal allocation of attention and the dynamics of prices depend on the firms' environment. As the variance of nominal aggregate demand increases, the firms' tracking problem becomes more difficult. Firms react by reallocating attention to aggregate conditions away from idiosyncratic conditions. In the new equilibrium, firms track both aggregate and idiosyncratic conditions less well. Their profits are lower. These results suggest that costs of aggregate instability in the real world may be due to the fact that aggregate instability makes the firms' tracking problem more difficult. As the variance of the idiosyncratic state variables increases, firms react by reallocating attention to idiosyncratic conditions away from aggregate conditions. Thus the model predicts that firms operating in more variable idiosyncratic environments track aggregate conditions less well.

Sims (1998) argues for modeling agents' inertial behavior as arising from agents' inability to pay attention to all available information. Sims (2003) derives some implications of limited information-processing capacity by adding information flow constraints to linear-quadratic optimization problems. The firms' decision problem of what to observe in our model is, after a log-quadratic approximation to the profit function, similar to the quadratic

control problem with an information flow constraint studied in Sims (2003, Section 4). One important difference is that firms in our model track an endogenous variable – the aggregate price level. This introduces the feedback effect described above.⁴

Our work is also related to the literature on information imperfections and the real effects of monetary policy. In Lucas (1973) firms observe prices in their markets but not the aggregate price level. Firms misinterpret unexpected inflation for a relative price increase and react by raising output, until the monetary policy shock becomes public information. Since information on monetary policy is published with little delay, it has been argued that the Lucas model cannot explain persistent real effects of monetary policy shocks. However, Sims (1998) points out that, if agents have limited information-processing capacity, then there is a difference between publicly available information and the information of which decisionmakers are actually aware. Woodford (2002) uses this idea to motivate a model in which firms observe nominal aggregate demand with exogenous idiosyncratic noise. If strategic complementarity in price setting is strong, the real effects of a nominal shock can be large and persistent. Woodford assumes that firms pay little attention to aggregate conditions. In contrast, we identify the conditions under which firms find it optimal to pay little attention to aggregate conditions and we study how the optimal allocation of attention and the dynamics of prices vary with changes in the firms' environment.⁵ Mankiw and Reis (2002) develop a different model in which information disseminates slowly. Mankiw and Reis assume that every period an exogenous fraction of firms obtains perfect information about all current and past disturbances, while all other firms continue to set prices based on old information. Reis (2004) shows that a model with a fixed cost of obtaining perfect information can provide a microfoundation for this kind of slow diffusion of information. In Mankiw and Reis (2002) and Reis (2004), prices react with equal speed to all disturbances.

⁴Moscarini (2004) studies a univariate quadratic control problem with an information flow constraint. In contrast to Sims (2003), Moscarini assumes that the decisionmaker can only meet the information flow constraint by infrequent sampling. Moscarini analyzes the optimal sampling frequency. The information that the decisionmaker receives once he or she samples is given exogenously. Other recent work following Sims (2003) includes Luo (2005) and Van Nieuwerburgh and Veldkamp (2005 a,b).

⁵Woodford's (2002) model has been extended in a number of directions. Hellwig (2002) studies the role of public information. Gumbau-Brisa (2003) studies the effects of a Taylor rule. Adam (2004) studies optimal monetary policy.

In contrast, in our model firms optimally decide to receive more precise information concerning some shocks and less precise information concerning other shocks implying that prices react quickly to some shocks and slowly to other shocks. For this reason the model can explain both the micro and the macro evidence on consumer prices. Note that in a model with a fixed cost of obtaining information, the cost of obtaining information is independent of the stochastic properties of the variables to be tracked. In contrast, in a model with an information flow constraint, tracking a variable with a higher variance well uses up a larger fraction of the available information flow.

The rest of the paper is organized as follows. Section 2 presents the model. Section 3 derives the firms' price setting behavior for given information. In Section 4 we solve a special case of the model analytically. In Sections 5 and 6 we return to the model in its general form. In Section 5 we study the firms' decision problem of what to observe. In Section 6 we compute the rational expectations equilibrium for a variety of different economies. Section 7 concludes. Appendix A introduces the tools that we use to state the firms' information flow constraint. The remaining appendices contain the proofs of the results used in the main text and details of how to solve the model numerically.

2 The model

2.1 Description of the economy

Consider an economy with a continuum of firms indexed by $i \in [0, 1]$. Time is discrete and indexed by t .

Firm i sells a good also indexed by i . Every period $t = 1, 2, \dots$, the firm sets the price of the good, P_{it} , so as to maximize

$$E_{it} \left[\sum_{T=t}^{\infty} \beta^{T-t} \pi(P_{iT}, P_T, Y_T, Z_{iT}) \right], \quad (1)$$

where E_{it} is the expectation operator conditioned on the information of firm i in period t , β is a scalar between zero and unity and $\pi(P_{it}, P_t, Y_t, Z_{it})$ are real profits of firm i in period t . Real profits depend on the price set by the firm, P_{it} , the aggregate price level, P_t , real aggregate demand, Y_t , and an idiosyncratic state variable, Z_{it} . The idiosyncratic state

variable reflects consumers' valuation of good i or the firm-specific state of technology. We assume that the function π is twice continuously differentiable and homogenous of degree zero in its first two arguments, i.e., real profits only depend on the relative price P_{it}/P_t . We also assume that the function π is a single-peaked function of P_{it} for given P_t , Y_t and Z_{it} .⁶

The information of firm i in period t is given by the sequence of all signals that the firm has received up to that point in time

$$s_i^t = \{s_i^1, s_{i2}, \dots, s_{it}\}, \quad (2)$$

where s_{it} denotes the signal that firm i receives in period t . The signal can be vector valued. We allow for the possibility that the firm receives a whole sequence of signals in period one, denoted s_i^1 .

Firms can change prices every period at no cost. Furthermore, firms take the stochastic processes for the aggregate price level, $\{P_t\}$, real aggregate demand, $\{Y_t\}$, and the idiosyncratic state variables, $\{Z_{it}\}$, as given. These assumptions imply that the price setting problem of firm i in period t is a purely static problem

$$\max_{P_{it}} E_{it}[\pi(P_{it}, P_t, Y_t, Z_{it})]. \quad (3)$$

The aggregate environment of firms is specified by postulating an exogenous stochastic process for nominal aggregate demand.⁷ Let

$$Q_t \equiv P_t Y_t \quad (4)$$

denote nominal aggregate demand. Let $q_t \equiv \ln Q_t - \ln \bar{Q}$ denote the log-deviation of nominal aggregate demand from its deterministic trend. We assume that q_t follows a stationary Gaussian process with mean zero and absolutely summable autocovariances.

⁶For example, in a standard model with Dixit-Stiglitz preferences and monopolistic competition

$$\pi(P_{it}, P_t, Y_t, Z_{it}) = Y_t \left(\frac{P_{it}}{P_t} \right)^{1-\theta} - C \left(Y_t \left(\frac{P_{it}}{P_t} \right)^{-\theta}, Y_t, Z_{it} \right),$$

where Y_t is the Dixit-Stiglitz consumption aggregator, P_t is the corresponding price index and $Y_t \left(\frac{P_{it}}{P_t} \right)^{-\theta}$ with $\theta > 1$ is the demand for good i . Real production costs C depend on the firm's output and may also depend on real aggregate demand through factor prices. Here Z_{it} affects productivity. If $C_{11} \geq 0$ then the function π is a single-peaked function of P_{it} for given P_t , Y_t and Z_{it} .

⁷This approach is common in the literature. For example, Lucas (1973), Woodford (2002), Mankiw and Reis (2002) and Reis (2004) also postulate an exogenous stochastic process for nominal aggregate demand.

The log of the aggregate price level is defined as

$$\ln P_t \equiv \int_0^1 \ln P_{it} di. \quad (5)$$

One obtains the same equation in a standard model of monopolistic competition after a log-linearization.⁸

The idiosyncratic environment of firms is specified by postulating an exogenous stochastic process for the idiosyncratic state variables. Let $z_{it} \equiv \ln Z_{it} - \ln \bar{Z}$ denote the log-deviation of idiosyncratic state variable i from its deterministic trend. We assume that the processes $\{z_{it}\}$, $i \in [0, 1]$, are pairwise independent and independent of $\{q_t\}$. Furthermore, we assume that the z_{it} , $i \in [0, 1]$, follow a common stationary Gaussian process with mean zero and absolutely summable autocovariances. Since the z_{it} , $i \in [0, 1]$, for given t are pairwise independent and identically distributed random variables with mean zero and finite variance, we have⁹

$$\int_0^1 z_{it} di = 0. \quad (6)$$

One could close the model by making an assumption about the information that firm i obtains in period t . This is what is typically done in the literature.¹⁰ In contrast, we want to capture the fact that firms can decide what to observe. We follow Sims (2003) in assuming that firms have limited information-processing ability and that firms use their information-processing ability optimally. Formally, in period zero we let each firm i , $i \in [0, 1]$, choose the stochastic process for the signal

$$\max_{\{s_{it}\} \in \Gamma} E \left[\sum_{t=1}^{\infty} \beta^t \pi(P_{it}^*, P_t, Y_t, Z_{it}) \right], \quad (7)$$

⁸In a standard model with Dixit-Stiglitz preferences and monopolistic competition, the aggregate price level is defined as $P_t \equiv \left(\int_0^1 P_{it}^{1-\theta} di \right)^{\frac{1}{1-\theta}}$. Log-linearizing this equation around any point with the property that all the P_{it} are equal yields equation (5).

⁹See Uhlig (1996), Theorem 2.

¹⁰For example, the perfect information case obtains when $s_{it} = (P_t, Y_t, Z_{it})'$ for all i, t . In a signal-extraction model, s_{it} would equal the variables of interest plus exogenous noise. In an information-delay model, $s_{it} = (P_{t-n}, Y_{t-n}, Z_{it-n})'$ for some integer $n > 0$. In a sticky-information model, $s_{it} = (P_1, \dots, P_t, Y_1, \dots, Y_t, Z_{i1}, \dots, Z_{it})'$ with some probability ρ and $s_{it} = s_{it-1}$ with probability $1 - \rho$.

subject to

$$P_{it}^* = \arg \max_{P_{it}} E[\pi(P_{it}, P_t, Y_t, Z_{it}) | s_i^t], \quad (8)$$

and

$$\mathcal{I}(\{P_t\}, \{Y_t\}, \{Z_{it}\}; \{s_{it}\}) \leq \kappa. \quad (9)$$

Firm i chooses the stochastic process for the signal (from the set Γ defined below) so as to maximize the expected discounted sum of future profits (7). The firm takes into account how the stochastic process for the signal affects its future price setting behavior (8). The firm has to respect the information flow constraint (9). The information flow constraint imposes an upper bound on the information flow between the sequence of signals and the sequence of variables of interest. The information flow between stochastic processes is defined in Appendix A. The firm cannot decide to observe all variables of interest perfectly in every period, but the firm can decide to observe some variable with a higher precision than another variable, as long as the total information flow does not exceed the parameter κ . The parameter κ indexes the firm's information-processing ability.¹¹

The set Γ is the set of all stochastic processes for the signal that have the following four properties. First, signals contain no information about future innovations to nominal aggregate demand and future innovations to the idiosyncratic state variables, i.e., signals contain no information about shocks that nature has not drawn yet. Second, the signal that firm i receives in period t is a vector that can be partitioned into a first subvector that only contains information about aggregate conditions and a second subvector that only contains information about idiosyncratic conditions. Formally,

$$s_{it} = (s_{1it}, s_{2it})', \quad (10)$$

where

$$\{s_{1it}, P_t, Y_t\} \text{ and } \{s_{2it}, Z_{it}\} \text{ are independent.} \quad (11)$$

The idea is that paying attention to aggregate conditions and paying attention to idiosyn-

¹¹In the model, the information-processing ability of firms is exogenous. It is straightforward to extend the model by specifying a cost function for κ and letting each firm choose the optimal κ .

cratic conditions are two separate activities.^{12 13} Third,

$$\{s_{1it}, s_{2it}, p_t, y_t, z_{it}\} \text{ is a stationary Gaussian vector process,} \quad (12)$$

where p_t , y_t and z_{it} denote the log-deviations of the aggregate price level, real aggregate demand and the idiosyncratic state variable i from their respective deterministic trends. Condition (12) can be justified as optimal. Gaussian signals in combination with Gaussian prior uncertainty yield Gaussian posterior uncertainty. Gaussian posterior uncertainty can be shown to be optimal when the optimization problem is linear-quadratic. We will show that after a log-quadratic approximation to the profit function the firms' optimization problem (7)-(9) has a linear-quadratic structure.^{14 15} Fourth, all noise in signals is idiosyncratic. This assumption accords well with the idea that the critical bottleneck is not the public availability of information but instead the inability of private agents to pay attention to all available information.

Finally, we make a simplifying assumption. We assume that firms receive a long sequence of signals in period one after having chosen the information system in period zero

$$s_i^1 = \{s_{i-\infty}, \dots, s_{i1}\}. \quad (13)$$

This assumption implies that the price set by a firm follows a stationary process. This simplifies the analysis.¹⁶

¹²Of course, condition (11) can only be satisfied when $\{P_t, Y_t\}$ and $\{Z_{it}\}$ are independent. We will verify that this is true in equilibrium.

¹³Consider a manager who has to set a price. The manager may inform himself by paying attention to different information sources. For example, the manager may read a financial newspaper or a marketing report. Reading a financial newspaper typically gives a lot of information about the aggregate state of the economy but gives very little information about whether customers like a particular good, what production of the good would cost and whether competitors might produce the good more cheaply. Reading a marketing report on the other hand gives a lot of information about tastes of customers but gives very little information about the aggregate state of the economy.

¹⁴Of course, condition (12) can only be satisfied when $\{p_t, y_t, z_{it}\}$ is a stationary Gaussian vector process. We will verify that this is true in equilibrium.

¹⁵Sims (2005) considers cases in which Gaussian posterior uncertainty is not optimal.

¹⁶One can show that observing a long sequence of signals in period one does not change the information flow in (9).

2.2 Equilibrium

An equilibrium of the model are stochastic processes for the signals, $\{s_{it}\}$, for the prices, $\{P_{it}\}$, for the aggregate price level, $\{P_t\}$, and for real aggregate demand, $\{Y_t\}$, such that:

1. Given $\{P_t\}$, $\{Y_t\}$ and $\{Z_{it}\}$, each firm $i \in [0, 1]$ chooses the stochastic process for the signal optimally in period $t = 0$ and sets the price for its good optimally in periods $t = 1, 2, \dots$
2. In every period $t = 1, 2, \dots$ and in every state of nature, the aggregate price level satisfies (5) and real aggregate demand satisfies (4).

3 Price setting behavior

In this section, we look at the firms' price setting behavior for given information.

The first-order condition for optimal price setting by firm i in period t is

$$E[\pi_1 (P_{it}^*, P_t, Y_t, Z_{it}) | s_i^t] = 0, \quad (14)$$

where π_1 denotes the derivative of the profit function π with respect to its first argument. In order to obtain a closed-form solution for the price set by the firm, we work with a log-quadratic approximation to the profit function around the non-stochastic solution of the model.

The solution of the non-stochastic version of the model is as follows. Suppose that $Q_t = \bar{Q}$ for all t and $Z_{it} = \bar{Z}$ for all i, t . In this case, there is no uncertainty and all firms solve the same price setting problem. Therefore in equilibrium

$$\pi_1 (P_t, P_t, Y_t, \bar{Z}) = 0. \quad (15)$$

Multiplying by $P_t > 0$ yields¹⁷

$$\pi_1 (1, 1, Y_t, \bar{Z}) = 0. \quad (16)$$

¹⁷Since the profit function π is homogeneous of degree zero in its first two arguments, the function π_1 is homogeneous of degree minus one in its first two arguments.

The solution to the last equation is equilibrium real aggregate demand, denoted \bar{Y} .¹⁸ The equilibrium aggregate price level, denoted \bar{P} , is given by

$$\bar{P} = \frac{\bar{Q}}{\bar{Y}}. \quad (17)$$

Next we compute the log-quadratic approximation to the profit function around the non-stochastic solution of the model. Let $x_t \equiv \ln X_t - \ln \bar{X}$ denote the log-deviation of a variable from its value at the non-stochastic solution. Using $X_t = \bar{X}e^{x_t}$ one can define the function $\hat{\pi}$ via $\hat{\pi}(p_{it}, p_t, y_t, z_{it}) = \pi(\bar{P}e^{p_{it}}, \bar{P}e^{p_t}, \bar{Y}e^{y_t}, \bar{Z}e^{z_{it}})$. Computing a second-order Taylor approximation to the function $\hat{\pi}$ around the point $(0, 0, 0, 0)$ yields the log-quadratic approximation to the profit function

$$\begin{aligned} \tilde{\pi}(p_{it}, p_t, y_t, z_{it}) &= \hat{\pi}(0, 0, 0, 0) + \hat{\pi}_1 p_{it} + \hat{\pi}_2 p_t + \hat{\pi}_3 y_t + \hat{\pi}_4 z_{it} \\ &+ \frac{\hat{\pi}_{11}}{2} p_{it}^2 + \frac{\hat{\pi}_{22}}{2} p_t^2 + \frac{\hat{\pi}_{33}}{2} y_t^2 + \frac{\hat{\pi}_{44}}{2} z_{it}^2 \\ &+ \hat{\pi}_{12} p_{it} p_t + \hat{\pi}_{13} p_{it} y_t + \hat{\pi}_{14} p_{it} z_{it} \\ &+ \hat{\pi}_{23} p_t y_t + \hat{\pi}_{24} p_t z_{it} + \hat{\pi}_{34} y_t z_{it}, \end{aligned} \quad (18)$$

where $\hat{\pi}_1$, for example, denotes the derivative of the function $\hat{\pi}$ with respect to its first argument evaluated at the point $(0, 0, 0, 0)$. It is straightforward to show that $\hat{\pi}_1 = 0$, $\hat{\pi}_{11} < 0$ and $\hat{\pi}_{12} = -\hat{\pi}_{11}$.

After the log-quadratic approximation to the profit function, the solution to the price setting problem of firm i in period t is¹⁹

$$p_{it}^* = E[p_t | s_i^t] + \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} E[y_t | s_i^t] + \frac{\hat{\pi}_{14}}{|\hat{\pi}_{11}|} E[z_{it} | s_i^t]. \quad (19)$$

The log of the price set by firm i in period t is a linear function of the conditional expectation of the log of the aggregate price level, the conditional expectation of the log of real aggregate demand and the conditional expectation of the log of the idiosyncratic state variable.

For comparison, the solution to the price setting problem of firm i in period t under perfect information is

$$p_{it}^f = p_t + \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} y_t + \frac{\hat{\pi}_{14}}{|\hat{\pi}_{11}|} z_{it}. \quad (20)$$

¹⁸We assume that equation (16) has a unique solution. For the profit function given in Footnote 6, a sufficient condition is $C_{11} + C_{12} > 0$.

¹⁹Set the derivative of $E[\tilde{\pi}(p_{it}, p_t, y_t, z_{it}) | s_i^t]$ with respect to p_{it} equal to zero and solve for p_{it} . Recall that $\hat{\pi}_1 = 0$, $\hat{\pi}_{11} < 0$ and $\hat{\pi}_{12} = -\hat{\pi}_{11}$. This yields equation (19).

Whenever the price (19) differs from the price (20) there is a loss in profits due to imperfect information. More precisely, the period t loss in profits due to imperfect information is

$$\tilde{\pi} \left(p_{it}^f, p_t, y_t, z_{it} \right) - \tilde{\pi} \left(p_{it}^*, p_t, y_t, z_{it} \right) = \frac{|\hat{\pi}_{11}|}{2} \left(p_{it}^f - p_{it}^* \right)^2. \quad (21)$$

The firm can affect this loss by deciding what to observe.

Before we turn to the firm's decision problem of what to observe, two additional observations will be helpful. First, let us define $\Delta_t \equiv p_t + \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} y_t$. The imperfect information price (19) and the perfect information price (20) can be expressed as

$$p_{it}^* = E[\Delta_t | s_i^t] + \frac{\hat{\pi}_{14}}{|\hat{\pi}_{11}|} E[z_{it} | s_i^t], \quad (22)$$

and

$$p_{it}^f = \Delta_t + \frac{\hat{\pi}_{14}}{|\hat{\pi}_{11}|} z_{it}. \quad (23)$$

These equations show that the variable Δ_t summarizes all that firms would like to know about aggregate conditions.

Second, computing the integral over all i of the perfect information price (20) and using equation (6) as well as $y_t = q_t - p_t$ yields the following expression for the aggregate price level under perfect information

$$p_t^f = \left(1 - \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} \right) p_t + \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} q_t. \quad (24)$$

The fixed point of this mapping is the equilibrium aggregate price level under perfect information. Assuming $\hat{\pi}_{13} \neq 0$, the unique fixed point is

$$p_t^f = q_t. \quad (25)$$

Hence, the equilibrium aggregate price level under perfect information moves one for one with nominal aggregate demand.

4 Analytical solution when exogenous processes are white noise

In this section, we solve the model under the assumption that log-deviations of nominal aggregate demand and log-deviations of the idiosyncratic state variables follow white noise

processes. In this special case, the model can be solved analytically. We illustrate the main mechanisms of the model with the help of this simple example. Afterwards, we solve the model under more realistic assumptions concerning the exogenous processes.

In this section, we assume that q_t follows a white noise process with variance $\sigma_q^2 > 0$ and the z_{it} , $i \in [0, 1]$, follow a common white noise process with variance $\sigma_z^2 > 0$. We guess that in equilibrium

$$p_t = \alpha q_t, \tag{26}$$

and

$$y_t = (1 - \alpha) q_t, \tag{27}$$

where $\alpha \in [0, 1]$. The guess will be verified.

Suppose that firm i can choose among signals of the form

$$s_{1it} = \Delta_t + \varepsilon_{it}, \tag{28}$$

$$s_{2it} = z_{it} + \psi_{it}, \tag{29}$$

where $\{\varepsilon_{it}\}$ and $\{\psi_{it}\}$ are idiosyncratic Gaussian white noise processes that are mutually independent and independent of $\{\Delta_t\}$ and $\{z_{it}\}$. When Δ_t and z_{it} follow white noise processes, one can restrict the firm's choice to signals of the form "true state plus white noise error term" without affecting the equilibrium of the model. This is proved below. See Proposition 3.²⁰

By devoting more or less attention to a variable the firm can affect the variance of noise in the respective signal. The firm has to respect the information flow constraint (9). Since the variables Δ_t , s_{1it} , z_{it} and s_{2it} follow white noise processes and since the variables p_t , y_t and Δ_t are perfectly correlated, the information flow constraint (9) can be expressed as

$$\frac{1}{2} \log_2 \left(\frac{\sigma_\Delta^2}{\sigma_\varepsilon^2} + 1 \right) + \frac{1}{2} \log_2 \left(\frac{\sigma_z^2}{\sigma_\psi^2} + 1 \right) \leq \kappa. \tag{30}$$

See Appendix B. The information flow constraint places a restriction on the signal-to-noise ratios, $\sigma_\Delta^2/\sigma_\varepsilon^2$ and σ_z^2/σ_ψ^2 . When the information flow constraint is binding, the firm faces

²⁰Note that one can make the signal (28) a signal concerning q_t , p_t or y_t by multiplying the signal with $\frac{1}{\alpha + \frac{\pi_{13}}{|\pi_{11}|}(1-\alpha)}$, $\frac{\alpha}{\alpha + \frac{\pi_{13}}{|\pi_{11}|}(1-\alpha)}$ or $\frac{1-\alpha}{\alpha + \frac{\pi_{13}}{|\pi_{11}|}(1-\alpha)}$, respectively. Of course, all these signals are associated with the same information flow and the same conditional expectation of Δ_t .

a trade-off: Increasing one signal-to-noise ratio requires reducing the other signal-to-noise ratio.

Let $\kappa_1 = \frac{1}{2} \log_2 \left(\frac{\sigma_\Delta^2}{\sigma_\varepsilon^2} + 1 \right)$ denote the information flow allocated to aggregate conditions. Let $\kappa_2 = \frac{1}{2} \log_2 \left(\frac{\sigma_z^2}{\sigma_\psi^2} + 1 \right)$ denote the information flow allocated to idiosyncratic conditions. Information flows κ_1 and κ_2 are associated with the following signal-to-noise ratios

$$\frac{\sigma_\Delta^2}{\sigma_\varepsilon^2} = 2^{2\kappa_1} - 1, \quad (31)$$

$$\frac{\sigma_z^2}{\sigma_\psi^2} = 2^{2\kappa_2} - 1. \quad (32)$$

These signal-to-noise ratios imply the following price setting behavior

$$\begin{aligned} p_{it}^* &= \frac{\sigma_\Delta^2}{\sigma_\Delta^2 + \sigma_\varepsilon^2} s_{1it} + \frac{\hat{\pi}_{14}}{|\hat{\pi}_{11}|} \frac{\sigma_z^2}{\sigma_z^2 + \sigma_\psi^2} s_{2it} \\ &= (1 - 2^{-2\kappa_1}) (\Delta_t + \varepsilon_{it}) + \frac{\hat{\pi}_{14}}{|\hat{\pi}_{11}|} (1 - 2^{-2\kappa_2}) (z_{it} + \psi_{it}), \end{aligned} \quad (33)$$

where the first equality follows from (22), (28) and (29) and the second equality follows from (31)-(32). This price setting behavior in turn is associated with the following expected discounted sum of losses in profits due to imperfect information

$$\begin{aligned} &E \left[\sum_{t=1}^{\infty} \beta^t \left\{ \tilde{\pi} \left(p_{it}^f, p_t, y_t, z_{it} \right) - \tilde{\pi} \left(p_{it}^*, p_t, y_t, z_{it} \right) \right\} \right] \\ &= \sum_{t=1}^{\infty} \beta^t \frac{|\hat{\pi}_{11}|}{2} E \left[\left(p_{it}^f - p_{it}^* \right)^2 \right] \\ &= \frac{\beta}{1 - \beta} \frac{|\hat{\pi}_{11}|}{2} \left\{ 2^{-2\kappa_1} \sigma_\Delta^2 + \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 2^{-2\kappa_2} \sigma_z^2 \right\}, \end{aligned} \quad (34)$$

where the first equality follows from (21) and the second equality follows from (23) and (31)-(33).

The optimal allocation of attention is therefore the solution to the strictly convex minimization problem

$$\min_{\kappa_1 \in [0, \kappa]} \frac{\beta}{1 - \beta} \frac{|\hat{\pi}_{11}|}{2} \left\{ 2^{-2\kappa_1} \sigma_\Delta^2 + \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 2^{-2(\kappa - \kappa_1)} \sigma_z^2 \right\}. \quad (35)$$

Assuming $\hat{\pi}_{14} \neq 0$, the unique solution to this problem is

$$\kappa_1^* = \begin{cases} \kappa & \text{if } x \geq 2^{2\kappa} \\ \frac{1}{2}\kappa + \frac{1}{4} \log_2(x) & \text{if } x \in [2^{-2\kappa}, 2^{2\kappa}] \\ 0 & \text{if } x \leq 2^{-2\kappa} \end{cases}, \quad (36)$$

where $x \equiv \sigma_{\Delta}^2 / \left(\left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 \sigma_z^2 \right)$. Hence, the solution to the firm's decision problem of what to observe is given by the signals (28)-(29) with signal-to-noise ratios (31)-(32) and optimal allocation of attention (36).

The attention allocated to aggregate conditions, κ_1^* , is increasing in x – the ratio of the variance of the perfect information price (23) due to aggregate shocks divided by the variance of the perfect information price (23) due to idiosyncratic shocks. When idiosyncratic conditions are more variable or more important for the price setting decision than aggregate conditions, firms pay more attention to idiosyncratic conditions than to aggregate conditions, $\kappa_1^* < (1/2)\kappa < \kappa_2^*$.²¹ In this case, the imperfect information price (33) reacts strongly to idiosyncratic shocks but only weakly to aggregate shocks. This can explain why individual prices change by large amounts and, at the same time, individual prices react little to aggregate shocks.

Computing the integral over all i of the price (33) yields the following expression for the aggregate price level

$$p_t^* = \left(1 - 2^{-2\kappa_1^*} \right) \Delta_t, \quad (37)$$

where the attention allocated to aggregate conditions is given by equation (36). The equilibrium aggregate price level is the fixed point of the mapping between the guess (26) and the actual law of motion (37). Assuming $0 < (\hat{\pi}_{13}/|\hat{\pi}_{11}|) \leq 1$, the unique fixed point is

$$p_t^* = \begin{cases} \frac{(2^{2\kappa} - 1) \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|}}{1 + (2^{2\kappa} - 1) \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|}} q_t & \text{if } \lambda \geq 2^{-\kappa} + (2^\kappa - 2^{-\kappa}) \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} \\ (1 - 2^{-\kappa} \lambda^{-1}) q_t & \text{if } \lambda \in \left[2^{-\kappa}, 2^{-\kappa} + (2^\kappa - 2^{-\kappa}) \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} \right] \\ 0 & \text{if } \lambda \leq 2^{-\kappa} \end{cases}, \quad (38)$$

where $\lambda \equiv \sqrt{\left(\frac{\hat{\pi}_{13}}{\hat{\pi}_{14}} \right)^2 \frac{\sigma_q^2}{\sigma_z^2}}$. The extent to which the equilibrium aggregate price level moves with nominal aggregate demand is increasing in λ . The reason is the optimal allocation of attention. For example, when the variance of the idiosyncratic state variables increases, firms pay more attention to idiosyncratic conditions and less attention to aggregate conditions. As a result, prices react less to innovations in nominal aggregate demand. In addition,

²¹More precisely, $\kappa_1^* < (1/2)\kappa < \kappa_2^*$ if and only if $x < 1$. The reason for $x < 1$ can be that idiosyncratic conditions are more variable ($\sigma_z^2 > \sigma_{\Delta}^2$) or that idiosyncratic conditions are more important for the price setting decision ($|\hat{\pi}_{14}/\hat{\pi}_{11}| > 1$) or both.

there is a feedback effect. When prices react less to innovations in nominal aggregate demand, the variance of the aggregate price level falls and therefore firms find it optimal to pay even less attention to aggregate conditions. Formally, when the variance of p_t falls, the variance of $\Delta_t = \left(1 - \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|}\right) p_t + \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} q_t$ falls and therefore κ_1^* falls. This makes prices react even less to innovations in nominal aggregate demand, and so on. The feedback effect is stronger the smaller is $(\hat{\pi}_{13}/|\hat{\pi}_{11}|)$. For this reason, λ depends on $\hat{\pi}_{13}$.

The feedback effect involving the optimal reallocation of attention is new in the literature. To illustrate its quantitative importance, consider a simple example. Suppose that $\sigma_q^2 = \sigma_z^2 = 10$, $(\hat{\pi}_{13}/|\hat{\pi}_{11}|) = 0.15$, $(\hat{\pi}_{14}/|\hat{\pi}_{11}|) = 1$ and $\kappa = 3$. If all other firms set the perfect information price, then $p_t = q_t$ and $\sigma_\Delta^2 = \sigma_q^2 = \sigma_z^2$. In this case, the optimal allocation of attention for an individual firm would be fifty-fifty, $\kappa_1 = \kappa_2 = (1/2)\kappa$. In equilibrium, the variance of p_t is smaller than the variance of q_t implying $\sigma_\Delta^2 < \sigma_q^2 = \sigma_z^2$. Therefore, in equilibrium, firms allocate only 20% of their attention to aggregate conditions.

Finally, if λ is very small or very large, the equilibrium allocation of attention is a corner solution. If λ is very small, firms allocate no attention to aggregate conditions and the aggregate price level equals its deterministic trend at each point in time. If λ is very large, firms allocate all attention to aggregate conditions.

It is straightforward to compute equilibrium real aggregate demand from the equilibrium aggregate price level (38) and the equation $y_t = q_t - p_t$.

5 The firms' decision of what to observe

Next we show how to solve the model in the general case when log-deviations of nominal aggregate demand and log-deviations of the idiosyncratic state variables follow stationary Gaussian moving average processes. In this section, we focus on the firms' decision problem of what to observe for given processes for the aggregate variables. In the next section, we compute the rational expectations equilibrium. We guess that in equilibrium

$$\{p_t, y_t\} \text{ and } \{z_{it}\} \text{ are independent, } \forall i \in [0, 1], \quad (39)$$

and

$$\{p_t, y_t\} \text{ is a stationary Gaussian vector process.} \quad (40)$$

These guesses will be verified in the next section.

The firm chooses the stochastic process for the signal so as to maximize the expected discounted sum of future profits (7).

Lemma 1 (*Expected discounted sum of profits*) *Let the profit function be given by (18) and suppose that (39)-(40) hold. Then*

$$E \left[\sum_{t=1}^{\infty} \beta^t \pi (P_{it}^*, P_t, Y_t, Z_{it}) \right] = E \left[\sum_{t=1}^{\infty} \beta^t \tilde{\pi} (p_{it}^f, p_t, y_t, z_{it}) \right] - \frac{\beta}{1-\beta} \frac{|\hat{\pi}_{11}|}{2} E \left[(p_{it}^f - p_{it}^*)^2 \right]. \quad (41)$$

Proof. See Appendix C. ■

The expected discounted sum of profits equals the expected discounted sum of profits under perfect information (the first term on the right-hand side) minus the expected discounted sum of losses in profits due to imperfect information (the second term on the right-hand side). The expected discounted sum of losses in profits due to imperfect information is increasing in the mean squared difference $E \left[(p_{it}^f - p_{it}^*)^2 \right]$. Therefore the firm chooses the stochastic process for the signal so as to minimize this mean squared difference.

The firm has to respect the information flow constraint (9).

Lemma 2 (*Information flows*) *Suppose that (39)-(40) hold. Then*

$$\mathcal{I}(\{P_t\}, \{Y_t\}, \{Z_{it}\}; \{s_{it}\}) = \mathcal{I}(\{p_t\}, \{y_t\}; \{s_{1it}\}) + \mathcal{I}(\{z_{it}\}; \{s_{2it}\}) \quad (42)$$

$$\geq \mathcal{I}(\{\Delta_t\}; \{s_{1it}\}) + \mathcal{I}(\{z_{it}\}; \{s_{2it}\}) \quad (43)$$

$$\geq \mathcal{I}(\{\Delta_t\}; \{\hat{\Delta}_{it}\}) + \mathcal{I}(\{z_{it}\}; \{\hat{z}_{it}\}), \quad (44)$$

where $\hat{\Delta}_{it} \equiv E[\Delta_t | s_{1i}^t]$ and $\hat{z}_{it} \equiv E[z_{it} | s_{2i}^t]$. If $s_{1it} = \Delta_t + \varepsilon_{it}$, where $\{\varepsilon_{it}\}$ is a stochastic process independent of $\{p_t\}$, then inequality (43) holds with equality. If $\{s_{1it}\}$ and $\{s_{2it}\}$ are univariate processes, then inequality (44) holds with equality.

Proof. See Appendix D. ■

Equality (42) says that the information flow between the signals and the variables of interest equals the information flow between the signals concerning aggregate conditions and aggregate conditions plus the information flow between the signals concerning idiosyncratic conditions and idiosyncratic conditions. This result follows from the independence

assumption (11) and implies that one can make statements of the sort: “The firm allocates X percent of the information flow to aggregate conditions and $1-X$ percent of the information flow to idiosyncratic conditions.” Inequality (43) states that the signals concerning aggregate conditions contain weakly more information about the aggregate price level and real aggregate demand than they contain about the variable Δ_t alone. The relationship holds with equality when the signals concerning aggregate conditions contain information about the variable Δ_t only. Inequality (44) states that the signals contain weakly more information than the conditional expectations computed from these signals. The relationship holds with equality when the signals are scalars.

Lemma 1, Lemma 2 and the price setting equations (22)-(23) imply that the firm’s decision problem of what to observe can be stated as follows.

Proposition 1 (*The decision problem*) *Let the profit function be given by (18) and suppose that (39)-(40) hold. Then the firm’s decision problem of what to observe can be stated as*

$$\min_{\{(s_{1it}, s_{2it})\} \in \Gamma} \left\{ E \left[(\Delta_t - \hat{\Delta}_{it})^2 \right] + \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 E \left[(z_{it} - \hat{z}_{it})^2 \right] \right\}, \quad (45)$$

subject to

$$\mathcal{I}(\{p_t\}, \{y_t\}; \{s_{1it}\}) + \mathcal{I}(\{z_{it}\}; \{s_{2it}\}) \leq \kappa. \quad (46)$$

Proof. See Appendix E. ■

After a log-quadratic approximation to the profit function, the firm’s decision problem of what to observe looks similar to the quadratic control problem with an information flow constraint studied in Sims (2003, Section 4). However, there are differences between the two problems. In Sims (2003, Section 4) the decisionmaker chooses a process for Y_t to track X_t with loss $E \left[(X_t - Y_t)^2 \right]$ subject to a constraint on the information flow between the two processes. Thus the same variables appear in the objective function and in the information flow constraint. In contrast, the firm’s objective function (45) depends on conditional expectations, $\hat{\Delta}_{it} = E \left[\Delta_t | s_{1i}^t \right]$ and $\hat{z}_{it} = E[z_{it} | s_{2i}^t]$, whereas the firm’s information flow constraint (46) applies to the underlying signal processes, $\{s_{1it}\}$ and $\{s_{2it}\}$. Furthermore, the problem of the firm is a collection of two quadratic control problems with a single information flow constraint. The firm has to decide how to allocate the total information flow across the

problem of tracking aggregate conditions and the problem of tracking idiosyncratic conditions.²² Finally, the firm tracks an endogenous variable, Δ_t . This introduces a feedback effect.

The following proposition presents a procedure for solving the firm's decision problem of what to observe.

Proposition 2 (*Solving the decision problem*) *Let the profit function be given by (18) and suppose that (39)-(40) hold. Then a stochastic process for the signal obtained by the following two-step procedure solves the firm's decision problem of what to observe.*

1. Derive stochastic processes $\{\hat{\Delta}_{it}^*\}$ and $\{\hat{z}_{it}^*\}$ that solve

$$\min_{\{\hat{\Delta}_{it}\}, \{\hat{z}_{it}\}} \left\{ E \left[(\Delta_t - \hat{\Delta}_{it})^2 \right] + \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 E \left[(z_{it} - \hat{z}_{it})^2 \right] \right\}, \quad (47)$$

subject to

$$\mathcal{I}(\{\Delta_t\}; \{\hat{\Delta}_{it}\}) + \mathcal{I}(\{z_{it}\}; \{\hat{z}_{it}\}) \leq \kappa, \quad (48)$$

$$\{\Delta_t, \hat{\Delta}_{it}\} \text{ and } \{z_{it}, \hat{z}_{it}\} \text{ are independent,} \quad (49)$$

$$\{\Delta_t, \hat{\Delta}_{it}, z_{it}, \hat{z}_{it}\} \text{ is a stationary Gaussian vector process.} \quad (50)$$

2. Show that there exist signals of the form

$$s_{1it} = \Delta_t + \varepsilon_{it}, \quad (51)$$

$$s_{2it} = z_{it} + \psi_{it}, \quad (52)$$

that have the property

$$\hat{\Delta}_{it}^* = E[\Delta_t | s_{1i}^t], \quad (53)$$

$$\hat{z}_{it}^* = E[z_{it} | s_{2i}^t], \quad (54)$$

where $\{\varepsilon_{it}\}$ and $\{\psi_{it}\}$ are idiosyncratic stationary Gaussian moving average processes that are mutually independent and independent of $\{p_t\}$, $\{y_t\}$ and $\{z_{it}\}$.

²²Sims (2003) considers multivariate tracking problems but only within the simplified recursive framework of Section 5 of his paper.

Proof. See Appendix F. ■

The first step consists of solving a standard constrained minimization problem. This is explained in Appendix H. The second step amounts to inverting a signal extraction problem. Instead of computing conditional expectations for given signals, we search for signals that generate certain processes as conditional expectations.

The processes $\{\hat{\Delta}_{it}\}$ and $\{\hat{z}_{it}\}$ that solve the program (47)-(50) have standard properties of a linear projection.

Proposition 3 (*Properties of a solution*) *A solution to the program (47)-(50) satisfies*

$$E \left[\Delta_t - \hat{\Delta}_{it}^* \right] = 0, \quad (55)$$

$$E [z_{it} - \hat{z}_{it}^*] = 0, \quad (56)$$

and, for all $k = 0, 1, 2, \dots$,

$$E \left[\left(\Delta_t - \hat{\Delta}_{it}^* \right) \hat{\Delta}_{it-k}^* \right] = 0, \quad (57)$$

$$E \left[\left(z_{it} - \hat{z}_{it}^* \right) \hat{z}_{it-k}^* \right] = 0. \quad (58)$$

Proof. See Appendix G. ■

This suggests that there exist signals that have the property (53)-(54). We will always verify numerically that such signals exist. In addition, Proposition 3 implies that, when Δ_t and z_{it} follow white noise processes, then $\hat{\Delta}_{it}^*$ and \hat{z}_{it}^* also follow white noise processes. In this case, one can restrict the firm's choice to signals of the form "true state plus white noise error term" without affecting the equilibrium of the model. We used this result in Section 4.

6 Numerical solutions when exogenous processes are serially correlated

In this section we show numerical solutions of the model. We compute the solutions as follows. First, we make a guess concerning the stochastic process for the aggregate price level. Second, we solve the firms' decision problem of what to observe. Namely, we derive the stochastic processes $\{\hat{\Delta}_{it}^*\}$ and $\{\hat{z}_{it}^*\}$ and we show that there exist signals of the form

(51)-(52) that have the property (53)-(54). See Proposition 2 and Appendix H. Third, we compute the individual prices from equation (22) and the aggregate price level from equation (5). Fourth, we compare the stochastic process for the aggregate price level that we obtain to our guess. We update the guess until a fixed point is reached.

6.1 The benchmark economy

See Table 1 for the parameter values of the benchmark economy. The ratio $(\hat{\pi}_{13}/|\hat{\pi}_{11}|)$ determines the sensitivity of individual prices to real aggregate demand, y_t . This is a standard parameter in models with monopolistic competition. Woodford (2003) recommends a value between 0.1 and 0.15. In the benchmark economy we set $(\hat{\pi}_{13}/|\hat{\pi}_{11}|) = 0.15$. Later we show how changes in $(\hat{\pi}_{13}/|\hat{\pi}_{11}|)$ affect the solution.

The ratio $(\hat{\pi}_{14}/|\hat{\pi}_{11}|)$ determines the sensitivity of individual prices to the idiosyncratic state variable, z_{it} . Since changes in the value of $(\hat{\pi}_{14}/|\hat{\pi}_{11}|)$ have the same effects on equilibrium as changes in the variance of the idiosyncratic state variable, we normalize $(\hat{\pi}_{14}/|\hat{\pi}_{11}|)$ to one and we only calibrate the variance of z_{it} .

We calibrate the stochastic process for q_t using quarterly U.S. nominal GNP data from 1959:1 to 2004:1.²³ We take the natural log of the data and detrend the data by fitting a second-order polynomial in time. We then estimate the equation $q_t = \rho q_{t-1} + \nu_t$, where q_t is 100 times the deviation of the natural log of nominal GNP from its fitted trend. The estimate of ρ that we obtain is, after rounding off, 0.95 and the standard deviation of the error term is 1. This implies the moving average representation $q_t = \sum_{l=0}^{\infty} \rho^l \nu_{t-l}$. Since with geometric decay shocks die out after a very large number of periods and computing time is fast increasing with the number of lags, we approximate the estimated process by a process that dies out after twenty periods: $q_t = \sum_{l=0}^{20} a_l \nu_{t-l}$, $a_0 = 1$ and $a_l = a_{l-1} - 0.05$, for all $l = 1, \dots, 20$.²⁴

We calibrate the stochastic process for z_{it} so as to make the model match the average absolute size of price changes in the data. Recall that Bils and Klenow (2004) find that the median firm changes its price every 4.3 months. Furthermore, Klenow and Kryvtsov (2004)

²³The source are the National Income and Product Accounts of the United States.

²⁴For the benchmark parameter values, we also solved the model without applying the approximation. We set $q_t = \sum_{l=0}^{80} \rho^l \nu_{t-l}$. While computing time was many times larger, the results were affected little.

find that, conditional on the occurrence of a price change, the average absolute size of the price change is 13.3% or 8.5% (depending on whether sales are included or excluded). We know from the analytical solution that a larger variance of the idiosyncratic state variables makes the aggregate price level more sticky. We also know that under rational inattention compared to perfect information a larger variance of the idiosyncratic state variables is required to generate a given average absolute size of price changes. We take a conservative approach and choose the standard deviation of z_{it} such that the average absolute size of price changes under perfect information is 8.5% per period.²⁵ This yields a standard deviation of z_{it} that is ten times the standard deviation of q_t .²⁶

We set the parameter that bounds the information flow to $\kappa = 3$ bits. Our choice is motivated by two considerations. First, $\kappa = 3$ is sizable compared to the amount of uncertainty in the model. If firms in the model wanted to, they could track aggregate conditions extremely well.²⁷ Second, with this value of κ the model predicts a negligible difference between the price set by a firm under rational inattention and the profit-maximizing price. We find this prediction realistic.

Table 1 and Figures 1-2 summarize the results for the benchmark economy. The average absolute size of price changes is 8.2% per period. Firms allocate 94% of their attention to idiosyncratic conditions. This optimal allocation of attention implies the following price setting behavior. Figure 1 shows the impulse response of the price set by firm i to an innovation in the idiosyncratic state variable i . Comparing the price reaction under rational inattention (the line with squares) to the price reaction under perfect information (the line with points), we see that under rational inattention the price reaction to idiosyncratic shocks is almost as strong and fast as under perfect information. The line with crosses is the impulse response of the price set by firm i to noise in the signal concerning idiosyncratic conditions.

Figure 2 shows the impulse response of the price set by firm i to an innovation in nominal

²⁵Recall that one period in the model is one quarter.

²⁶We assume the same rate of decay in the z_{it} process as in the q_t process.

²⁷To illustrate this point, consider a simple example. Suppose that q_t was a white noise process with variance 10, which is the variance of q_t in the data. Then allocating 3 bits of information flow to tracking q_t implies that the variance of q_t conditional on the signal is 0.15. Thus the variance is reduced by 98.5%.

aggregate demand. Comparing the price reaction under rational inattention (the line with squares) to the price reaction under perfect information (the line with points), we see that under rational inattention the price reaction to nominal shocks is dampened and delayed. Note that, since all firms choose the same stochastic process for the signal, the line with squares is also the impulse response of the aggregate price level to an innovation in nominal aggregate demand. The aggregate price level responds weakly and slowly to innovations in nominal aggregate demand. The reasons are the following. Since idiosyncratic conditions are more variable than aggregate conditions, firms allocate most of their attention to idiosyncratic conditions. In addition, there is the feedback effect. When firms pay little attention to aggregate conditions, the aggregate price level moves little and therefore firms find it optimal to pay even less attention to aggregate conditions. As a result, the equilibrium aggregate price level under rational inattention differs markedly from the equilibrium aggregate price level under perfect information. Finally, the line with crosses in Figure 2 is the impulse response of the price set by an individual firm to noise in the signal concerning aggregate conditions.²⁸

The effect of an innovation in nominal aggregate demand on real aggregate demand equals the difference between the perfect-information impulse response in Figure 2 and the rational-inattention impulse response in Figure 2. It is apparent that the real effect of an innovation in nominal aggregate demand is persistent.

Figures 3-4 show simulated price series. Figure 3 shows a sequence of prices set by an individual firm under rational inattention (diamonds) and the sequence of prices that the firm would have set if it had had perfect information (crosses). Firms in the benchmark economy track the profit-maximizing price extremely well. Figure 4 shows sequences

²⁸The reader interested in the impulse response of inflation to an innovation in nominal aggregate demand should note the following. In the benchmark economy, the peak response of inflation occurs on impact. Below we conduct experiments in which the impulse response of the aggregate price level becomes more dampened and delayed than in the benchmark economy. In these experiments, the impulse response of inflation becomes hump-shaped. See the experiment with a larger variance of the idiosyncratic state variables (section 6.3) and the experiment with more strategic complementarity in price setting (section 6.4). We read the evidence from structural VARs as indicating clearly that the aggregate price level responds slowly to a monetary policy shock. We read the evidence as less conclusive regarding whether the impulse response of inflation to a monetary policy shock is hump-shaped (see Uhlig (2005)).

of aggregate price levels. The equilibrium aggregate price level under rational inattention (diamonds) differs markedly from the equilibrium aggregate price level under perfect information (crosses). The reason is the optimal allocation of attention in combination with the feedback effect.

In the benchmark economy, prices react fast and by large amounts to idiosyncratic shocks, but prices react only slowly and by small amounts to nominal shocks. Thus the model can explain why individual prices change frequently and by large amounts and, at the same time, the aggregate price level responds slowly to monetary shocks. To match the large average absolute size of price changes observed in the data, idiosyncratic shocks in the model must have a large variance or must be very important for pricing decisions. This in turn implies that firms in the model allocate most of their attention to idiosyncratic conditions.

We turn to examining how changes in parameter values affect the optimal allocation of attention and the dynamics of the economy.

6.2 Increasing the variance of nominal aggregate demand

In Table 2 and Figure 5 we show what happens when the variance of nominal aggregate demand increases. Firms reallocate attention to aggregate conditions away from idiosyncratic conditions (κ_1^* increases). Firms track both aggregate and idiosyncratic conditions less well. Profits decrease. The real effects of changes in nominal aggregate demand increase. The fall in profits suggests that costs of aggregate instability in the real world may be due to the fact that aggregate instability makes the firms' tracking problem more difficult.

These predictions differ from the Lucas (1973) model. In the Lucas model, an increase in the variance of nominal aggregate demand implies that prices that firms observe in their markets become more precise signals of nominal aggregate demand and less precise signals of idiosyncratic conditions. Therefore firms in the Lucas model track nominal aggregate demand better and idiosyncratic conditions worse. The real effects of changes in nominal aggregate demand become smaller.

6.3 Increasing the variance of the idiosyncratic state variables

In Table 2 and Figure 6 we show what happens when the variance of the idiosyncratic state variables increases. Firms reallocate attention to idiosyncratic conditions away from aggregate conditions (κ_1^* decreases). Firms track both idiosyncratic and aggregate conditions less well. The reaction of the aggregate price level to a nominal shock becomes more dampened and delayed.

The model predicts that firms operating in more variable idiosyncratic environments allocate less attention to aggregate conditions, and therefore respond more slowly to aggregate shocks. This result is consistent with the empirical finding of Bils, Klenow and Kryvtsov (2003) according to which firms that change prices relatively frequently react *more slowly* to monetary policy shocks than firms that change prices relatively infrequently. The finding of Bils, Klenow and Kryvtsov is difficult to reconcile with other models of sticky prices.

The reader may wonder whether these predictions continue to hold in a model with an endogenous κ . Suppose that firms can choose the information flow, κ , facing an increasing, strictly convex cost function, $C(\kappa)$. Now consider again the effects of increasing the variance of the idiosyncratic state variables. The marginal value of information about idiosyncratic conditions increases. Therefore firms choose a higher κ and the marginal cost of information increases. This implies that the marginal value of information about aggregate conditions has to increase as well – the information flow allocated to aggregate conditions has to fall. Hence, both idiosyncratic and aggregate conditions get tracked less well.

6.4 Changing the degree of strategic complementarity in price setting

The third and fourth example in Table 2 and Figure 7 show what happens when the ratio $(\hat{\pi}_{13}/|\hat{\pi}_{11}|)$ changes.²⁹ As $(\hat{\pi}_{13}/|\hat{\pi}_{11}|)$ decreases, the impulse response of the aggregate price level becomes more dampened and delayed. The reason is the following. Under rational inattention, the aggregate price level is less variable than nominal aggregate demand. Thus decreasing $(\hat{\pi}_{13}/|\hat{\pi}_{11}|)$ lowers the variance of $\Delta_t = \left(1 - \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|}\right) p_t + \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} q_t$. Firms react by

²⁹It is common in the literature to refer to the ratio $(\hat{\pi}_{13}/|\hat{\pi}_{11}|)$ as a measure of the degree of strategic complementarity in price setting, where a smaller value of $(\hat{\pi}_{13}/|\hat{\pi}_{11}|)$ corresponds to a larger degree of strategic complementarity in price setting.

reallocating attention to idiosyncratic conditions away from aggregate conditions.

6.5 The effects of serial correlation

Decreasing the serial correlation of nominal aggregate demand (holding constant its variance) leads to a fall in profits, because the firms' tracking problem becomes more difficult. This suggests that there is a payoff from "interest rate smoothing" by central banks. We obtained ambiguous predictions concerning the effect of a decrease in the serial correlation of nominal aggregate demand (holding constant its variance) on the allocation of attention. We found that the marginal return from allocating attention to aggregate conditions may go up or down. The reason is that decreasing the serial correlation of nominal aggregate demand makes firms track aggregate conditions less well (for a given allocation of attention), but also lowers the improvement in tracking that can be achieved by reallocating attention to aggregate conditions.³⁰

6.6 Optimal signals

We always verify numerically that there exist signals of the form (51)-(52) that have the property (53)-(54). Figures 8 and 9 present optimal signals for the benchmark economy, by plotting the parameters of the moving average representations of Δ_t , ε_{it} , z_{it} and ψ_{it} . A common assumption in the literature is that signals have the form "true state plus i.i.d. noise". We always find optimal signals that have the structure "true state plus a moving average noise process". However, only in some cases we find optimal signals that have the structure "true state plus i.i.d. noise". For example, the optimal idiosyncratic signal depicted in Figure 9 has the form "true state plus i.i.d. noise", but the optimal aggregate signal shown in Figure 8 does not.³¹

³⁰We obtained the same results when we changed the serial correlation of the idiosyncratic state variables.

³¹Note that optimal signals are not unique. For example, applying any one-sided linear filter to the signals depicted in Figures 8 and 9 yields new optimal signals. The reason is that applying a one-sided linear filter changes neither the conditional expectations computed from the signals nor the information flow.

7 Conclusions and further research

That individual prices move frequently and by large amounts in the data does *not* imply that the aggregate price level must react fast to monetary policy shocks. When idiosyncratic conditions are more variable or more important than aggregate conditions, rationally inattentive firms optimally allocate more attention to idiosyncratic conditions than to aggregate conditions. As a result, prices react fast and by large amounts to idiosyncratic shocks, but prices react only slowly and by small amounts to nominal shocks. Innovations in nominal aggregate demand have persistent real effects.

In standard sticky price models, frequent and large price changes imply a *fast* response of the aggregate price level to nominal shocks. In our model, frequent and large price changes imply a *slow* response of the aggregate price level to nominal shocks. The *same* empirical observation on the frequency and size of individual price changes leads to the *opposite* aggregate prediction. Therefore our model can simultaneously explain the micro and the macro evidence on consumer prices.

Our model makes several testable predictions that we plan to compare to data. For example, according to the model, firms operating in more variable idiosyncratic environments react more slowly to nominal shocks.

The model can be extended in a variety of directions. For example, the model in its current form abstracts from physical costs of repricing. This implies that prices in the model change every period. It would be interesting to add menu costs. This is likely to increase the real effects of nominal disturbances even further.³²

Furthermore, it will be interesting to develop a richer general equilibrium model with rational inattention and compare its predictions to, for example, Christiano, Eichenbaum and Evans (2005), Altig, Christiano, Eichenbaum and Linde (2005) and Smets and Wouters (2003).

³²See Dotsey, King and Wolman (1999) and Golosov and Lucas (2005) for general equilibrium models with menu costs.

A Quantifying information flows

This appendix introduces the tools that we use to quantify information flows. We borrow the tools from Shannon’s (1948) information theory. For a textbook on information theory, see Cover and Thomas (1991). For an application in economics, see Sims (2003).

In economics the payoff of a decisionmaker often depends on the realization of a random variable. One can quantify the uncertainty by using the concept of *entropy*. The entropy of a random variable is a measure of the uncertainty of the random variable. The entropy $H(X)$ of a random variable X with density function $p(X)$ is defined by $H(X) = -E[\log_2 p(X)]$. Entropy is measured in bits. For example, the entropy of a normally distributed random variable X with variance σ^2 is

$$H(X) = \frac{1}{2} \log_2 (2\pi e \sigma^2).$$

In this simple example, entropy is a strictly increasing function of the variance.³³

The definition of entropy extends to random vectors. In the definition of entropy, simply replace the density function by the joint density function. For example, applying the definition of entropy to a set of random variables X_1, \dots, X_T that have a multivariate normal distribution with covariance matrix Ω_{XX} yields

$$H(X_1, \dots, X_T) = \frac{1}{2} \log_2 [(2\pi e)^T \det \Omega_{XX}]. \quad (59)$$

The entropy of the random vector depends on the number of random variables and on their covariance matrix. A larger determinant of the covariance matrix implies a larger entropy. For given variances, the entropy is largest when the random variables are uncorrelated.

In economics a decisionmaker often observes a random vector that is correlated with the random vector of interest. One can quantify the conditional uncertainty by using the concept of *conditional entropy*. For example, suppose that a decisionmaker is interested in X_1, \dots, X_T and observes Y_1, \dots, Y_T , where X_1, \dots, X_T and Y_1, \dots, Y_T have a multivariate normal distribution with covariance matrix Ω . Then the entropy of X_1, \dots, X_T conditional

³³The definition of entropy can be derived from axioms – requirements that a “reasonable” measure of uncertainty should satisfy (see e.g. Ash (1990)). Moreover, entropy arises as the answer to a number of natural questions in communication theory and statistics (see e.g. Cover and Thomas (1991)).

on Y_1, \dots, Y_T is

$$H(X_1, \dots, X_T | Y_1, \dots, Y_T) = \frac{1}{2} \log_2 \{ (2\pi e)^T \det[\Omega_{XX} - \Omega_{XY} \Omega_{YY}^{-1} \Omega_{YX}] \}. \quad (60)$$

The expression in square brackets is the covariance matrix of X_1, \dots, X_T conditional on Y_1, \dots, Y_T .

Now one can quantify the amount of information that one random vector contains about another random vector. *Mutual information* is the reduction in the uncertainty of one random vector due to the knowledge of another random vector. The mutual information between X_1, \dots, X_T and Y_1, \dots, Y_T is

$$I(X_1, \dots, X_T; Y_1, \dots, Y_T) = H(X_1, \dots, X_T) - H(X_1, \dots, X_T | Y_1, \dots, Y_T). \quad (61)$$

It is also straightforward to quantify the information flow between stochastic processes. Let X_1, \dots, X_T denote the first T elements of the stochastic process $\{X_t\}$. Let Y_1, \dots, Y_T denote the first T elements of the stochastic process $\{Y_t\}$. The processes $\{X_t\}$ and $\{Y_t\}$ can be vector processes. The information flow between the processes $\{X_t\}$ and $\{Y_t\}$ can be defined by

$$\mathcal{I}(\{X_t\}; \{Y_t\}) = \lim_{T \rightarrow \infty} \frac{1}{T} I(X_1, \dots, X_T; Y_1, \dots, Y_T). \quad (62)$$

The information flow between stochastic processes is the average amount of information per unit of time that one stochastic process contains about another stochastic process. The limit in (62) exists when the processes $\{X_t\}$ and $\{Y_t\}$ are jointly stationary.

In the Gaussian case, an analytical expression exists for the information flow. If $\{X_t\}$ and $\{Y_t\}$ are univariate, jointly stationary, jointly Gaussian processes with absolutely summable autocovariance matrices then

$$\mathcal{I}(\{X_t\}; \{Y_t\}) = -\frac{1}{4\pi} \int_{-\pi}^{\pi} \log_2 [1 - \mathcal{C}_{X,Y}(\omega)] d\omega, \quad (63)$$

where $\mathcal{C}_{X,Y}(\omega)$ is the coherence between the processes $\{X_t\}$ and $\{Y_t\}$ at frequency ω . This follows from equations (59)-(62) and the asymptotic properties of determinants of Toeplitz matrices. See Cover and Thomas (1991, pp. 273-274), Gray (2002, pp. 62-63) or Sims (2003). Note that the coherence lies between zero and one, $0 \leq \mathcal{C}_{X,Y}(\omega) \leq 1$ for all ω . It follows that the information flow in (63) is bounded below by zero and is unbounded above.

B Information flow constraint in the white noise case

Assumptions (10)-(11) imply

$$\mathcal{I}(\{P_t\}, \{Y_t\}, \{Z_{it}\}; \{s_{it}\}) = \mathcal{I}(\{p_t\}, \{y_t\}; \{s_{1it}\}) + \mathcal{I}(\{z_{it}\}; \{s_{2it}\}).$$

This general result is proved below. See Lemma 2. Furthermore, equations (26)-(27) imply that $\{p_t\}$ and $\{y_t\}$ can be calculated from $\{\Delta_t\}$ and vice versa. It follows that

$$\mathcal{I}(\{p_t\}, \{y_t\}; \{s_{1it}\}) = \mathcal{I}(\{\Delta_t\}; \{s_{1it}\}).$$

The signal concerning aggregate conditions is given by equation (28). Equation (63) implies that

$$\mathcal{I}(\{\Delta_t\}; \{s_{1it}\}) = -\frac{1}{4\pi} \int_{-\pi}^{\pi} \log_2 [1 - \mathcal{C}_{\Delta, s_{1i}}(\omega)] d\omega,$$

where $\mathcal{C}_{\Delta, s_{1i}}(\omega)$ is the coherence between the processes $\{\Delta_t\}$ and $\{s_{1it}\}$ at frequency ω . The processes $\{\Delta_t\}$ and $\{s_{1it}\}$ are white noise processes. Therefore the coherence simply equals the squared correlation coefficient and

$$\mathcal{I}(\{\Delta_t\}; \{s_{1it}\}) = -\frac{1}{2} \log_2 (1 - \rho_{\Delta, s_{1i}}^2).$$

Using (28) yields

$$\mathcal{I}(\{\Delta_t\}; \{s_{1it}\}) = \frac{1}{2} \log_2 \left(\frac{\sigma_{\Delta}^2}{\sigma_{\varepsilon}^2} + 1 \right).$$

The same arguments yield

$$\mathcal{I}(\{z_{it}\}; \{s_{2it}\}) = \frac{1}{2} \log_2 \left(\frac{\sigma_z^2}{\sigma_{\psi}^2} + 1 \right).$$

The information flow constraint becomes

$$\frac{1}{2} \log_2 \left(\frac{\sigma_{\Delta}^2}{\sigma_{\varepsilon}^2} + 1 \right) + \frac{1}{2} \log_2 \left(\frac{\sigma_z^2}{\sigma_{\psi}^2} + 1 \right) \leq \kappa.$$

C Proof of lemma 1

When the profit function is given by equation (18), the expected discounted sum of profits equals

$$\begin{aligned} E \left[\sum_{t=1}^{\infty} \beta^t \pi (P_{it}^*, P_t, Y_t, Z_{it}) \right] &= E \left[\sum_{t=1}^{\infty} \beta^t \tilde{\pi} (p_{it}^*, p_t, y_t, z_{it}) \right] \\ &= E \left[\sum_{t=1}^{\infty} \beta^t \tilde{\pi} (p_{it}^f, p_t, y_t, z_{it}) \right] - E \left[\sum_{t=1}^{\infty} \beta^t \frac{|\hat{\pi}_{11}|}{2} (p_{it}^f - p_{it}^*)^2 \right], \end{aligned}$$

where the second equality follows from equation (21). The difference between the perfect information price (20) and the imperfect information price (19) equals

$$p_{it}^f - p_{it}^* = p_{it}^f - E [p_{it}^f | s_i^t].$$

The joint normality of p_{it}^f and $s_i^t = \{s_i^1, s_{i2}, \dots, s_{it}\}$ implies that the conditional expectation equals the linear projection. Furthermore, the joint stationarity of $\{p_{it}^f\}$ and $\{s_{it}\}$ in combination with assumption (13) implies that the linear projection coefficients are independent of t

$$p_{it}^f - p_{it}^* = p_{it}^f - [\mu + \alpha(L) s_{it}],$$

where μ is a constant and $\alpha(L)$ is an infinite order vector lag polynomial. Hence, $p_{it}^f - p_{it}^*$ follows a stationary process and $E \left[(p_{it}^f - p_{it}^*)^2 \right]$ is independent of t . Equation (41) follows.

D Proof of lemma 2

First, since $\{P_t\}, \{Y_t\}, \{Z_{it}\}$ can be calculated from $\{p_t\}, \{y_t\}, \{z_{it}\}$ and vice versa, we have

$$\mathcal{I}(\{P_t\}, \{Y_t\}, \{Z_{it}\}; \{s_{it}\}) = \mathcal{I}(\{p_t\}, \{y_t\}, \{z_{it}\}; \{s_{it}\}).$$

Applying the definition of information flow (62) yields

$$\mathcal{I}(\{p_t\}, \{y_t\}, \{z_{it}\}; \{s_{it}\}) = \lim_{T \rightarrow \infty} \frac{1}{T} I(p^T, y^T, z_i^T; s_i^T),$$

where $p^T \equiv (p_1, \dots, p_T)$, $y^T \equiv (y_1, \dots, y_T)$, $z_i^T \equiv (z_{i1}, \dots, z_{iT})$ and $s_i^T \equiv (s_i^1, s_{i2}, \dots, s_{iT})$.

Mutual information equals the difference between entropy and conditional entropy

$$I(p^T, y^T, z_i^T; s_i^T) = H(p^T, y^T, z_i^T) - H(p^T, y^T, z_i^T | s_i^T).$$

See equation (61). Conditional entropy equals

$$H(p^T, y^T, z_i^T | s_i^T) = H(p^T, y^T, z_i^T, s_i^T) - H(s_i^T).$$

See, for example, Cover and Thomas (1991), p. 230, equation (9.33). We arrive at

$$I(p^T, y^T, z_i^T; s_i^T) = H(p^T, y^T, z_i^T) - H(p^T, y^T, z_i^T, s_i^T) + H(s_i^T).$$

Assumption (10) implies

$$I(p^T, y^T, z_i^T; s_i^T) = H(p^T, y^T, z_i^T) - H(p^T, y^T, z_i^T, s_{1i}^T, s_{2i}^T) + H(s_{1i}^T, s_{2i}^T).$$

The entropy of independent random variables or independent random vectors equals the sum of the entropies. See, for example, Cover and Thomas (1991), p. 232, equation (9.59).

Therefore assumption (11) implies

$$\begin{aligned} I(p^T, y^T, z_i^T; s_i^T) &= H(p^T, y^T) + H(z_i^T) - H(p^T, y^T, s_{1i}^T) - H(z_i^T, s_{2i}^T) \\ &\quad + H(s_{1i}^T) + H(s_{2i}^T). \end{aligned}$$

The last equation can also be expressed as

$$I(p^T, y^T, z_i^T; s_i^T) = I(p^T, y^T; s_{1i}^T) + I(z_i^T; s_{2i}^T).$$

Dividing by T on both sides and taking the limit as $T \rightarrow \infty$ yields

$$\mathcal{I}(\{p_t\}, \{y_t\}, \{z_{it}\}; \{s_{it}\}) = \mathcal{I}(\{p_t\}, \{y_t\}; \{s_{1it}\}) + \mathcal{I}(\{z_{it}\}; \{s_{2it}\}).$$

Second, since $\{p_t\}, \{y_t\}$ can be calculated from $\{p_t\}, \{\Delta_t\}$ and vice versa, we have

$$\mathcal{I}(\{p_t\}, \{y_t\}; \{s_{1it}\}) = \mathcal{I}(\{p_t\}, \{\Delta_t\}; \{s_{1it}\}).$$

Applying the definition of information flow (62) yields

$$\mathcal{I}(\{p_t\}, \{\Delta_t\}; \{s_{1it}\}) = \lim_{T \rightarrow \infty} \frac{1}{T} I(p^T, \Delta^T; s_{1i}^T).$$

Mutual information equals the difference between entropy and conditional entropy

$$I(p^T, \Delta^T; s_{1i}^T) = H(p^T, \Delta^T) - H(p^T, \Delta^T | s_{1i}^T).$$

See equation (61). The following conditional entropies can be expressed as

$$\begin{aligned} H(p^T|\Delta^T) &= H(p^T, \Delta^T) - H(\Delta^T), \\ H(p^T|\Delta^T, s_{1i}^T) &= H(p^T, \Delta^T|s_{1i}^T) - H(\Delta^T|s_{1i}^T). \end{aligned}$$

See, for example, Cover and Thomas (1991), p. 230, equation (9.33). We arrive at

$$I(p^T, \Delta^T; s_{1i}^T) = H(\Delta^T) + H(p^T|\Delta^T) - H(\Delta^T|s_{1i}^T) - H(p^T|\Delta^T, s_{1i}^T).$$

The last equation can also be expressed as

$$I(p^T, \Delta^T; s_{1i}^T) = I(\Delta^T; s_{1i}^T) + I(p^T; s_{1i}^T|\Delta^T).$$

Furthermore, mutual information is non-negative

$$I(p^T; s_{1i}^T|\Delta^T) \geq 0,$$

with equality if and only if p^T and s_{1i}^T are conditionally independent given Δ^T . See, for example, Cover and Thomas (1991), p. 232, first corollary to theorem 9.6.1. Hence,

$$\mathcal{I}(\{p_t\}, \{\Delta_t\}; \{s_{1it}\}) \geq \mathcal{I}(\{\Delta_t\}; \{s_{1it}\}),$$

with equality if p^T and s_{1i}^T are conditionally independent given Δ^T for all T .

Third, applying the definition of information flow (62) yields

$$\mathcal{I}(\{z_{it}\}; \{s_{2it}\}) = \lim_{T \rightarrow \infty} \frac{1}{T} I(z_i^T; s_{2i}^T).$$

Mutual information equals the difference between entropy and conditional entropy

$$I(z_i^T; s_{2i}^T) = H(z_i^T) - H(z_i^T|s_{2i}^T).$$

See equation (61). Since $\hat{z}_i^T \equiv (\hat{z}_{i1}, \dots, \hat{z}_{iT})$ can be calculated from s_{2i}^T , we have

$$H(z_i^T|s_{2i}^T) = H(z_i^T|s_{2i}^T, \hat{z}_i^T).$$

Since conditioning reduces entropy, we have

$$H(z_i^T|s_{2i}^T, \hat{z}_i^T) \leq H(z_i^T|\hat{z}_i^T).$$

See, for example, Cover and Thomas (1991), p. 232, second corollary to theorem 9.6.1. We arrive at

$$I(z_i^T; s_{2i}^T) \geq I(z_i^T; \hat{z}_i^T).$$

Dividing by T on both sides and taking the limit as $T \rightarrow \infty$ yields

$$\mathcal{I}(\{z_{it}\}; \{s_{2it}\}) \geq \mathcal{I}(\{z_{it}\}; \{\hat{z}_{it}\}).$$

The same arguments yield

$$\mathcal{I}(\{\Delta_t\}; \{s_{1it}\}) \geq \mathcal{I}(\{\Delta_t\}; \{\hat{\Delta}_{it}\}).$$

Next, suppose that $\{s_{1it}\}$ is a univariate process. Then

$$\hat{\Delta}_{it} = \mu_1 + \alpha_1(L) s_{1it},$$

where μ_1 is a constant and $\alpha_1(L)$ is an infinite order lag polynomial. See proof of Lemma 1. Thus $\{\hat{\Delta}_{it}\}$ is obtained from $\{s_{1it}\}$ by applying a one-sided linear filter (and possibly adding a constant). Standard results on linear filters imply

$$\mathcal{C}_{\Delta, \hat{\Delta}_i}(\omega) = \mathcal{C}_{\Delta, s_{1i}}(\omega),$$

where $\mathcal{C}_{\Delta, \hat{\Delta}_i}(\omega)$ denotes the coherence between the processes $\{\Delta_t\}$ and $\{\hat{\Delta}_{it}\}$ at frequency ω . This result in combination with equation (63) yields

$$\mathcal{I}(\{\Delta_t\}; \{\hat{\Delta}_{it}\}) = \mathcal{I}(\{\Delta_t\}; \{s_{1it}\}).$$

The same arguments yield that, if $\{s_{2it}\}$ is a univariate process, then

$$\mathcal{I}(\{z_{it}\}; \{\hat{z}_{it}\}) = \mathcal{I}(\{z_{it}\}; \{s_{2it}\}).$$

E Proof of proposition 1

The objective function (45) follows from Lemma 1, the price setting equations (22)-(23) and the orthogonality of $\Delta_t - \hat{\Delta}_{it}$ and $z_{it} - \hat{z}_{it}$. The information flow constraint (46) follows from equation (42).

F Proof of proposition 2

When the profit function is given by equation (18) and (39)-(40) hold, the firm's decision problem of what to observe is given by the program (45)-(46). See Proposition 1. The objective functions (45) and (47) are identical. The information flow constraint (46) implies inequality (48). See Lemma 2. The definition of the set Γ and assumption (13) imply conditions (49)-(50). It follows that a solution to the program (45)-(46) cannot make the firm better off than a solution to the program (47)-(50).

Second, signals of the form (51)-(52) are an element of the set Γ . Furthermore, in the case of signals of the form (51)-(52), inequalities (43)-(44) hold with equality. Hence, if signals of the form (51)-(52) have the property (53)-(54), then they satisfy the information flow constraint (46) and they are a solution to the program (45)-(46).

G Proof of proposition 3

First, the mean of the process $\{\hat{\Delta}_{it}\}$ affects $E\left[\left(\Delta_t - \hat{\Delta}_{it}\right)^2\right]$ but does not affect the information flow $\mathcal{I}\left(\{\Delta_t\}; \{\hat{\Delta}_{it}\}\right)$. See equation (63). Therefore a solution to the program (47)-(50) has to satisfy

$$E\left[\hat{\Delta}_{it}^*\right] = E\left[\Delta_t\right].$$

The same arguments yield that a solution to the program (47)-(50) has to satisfy

$$E\left[\hat{z}_{it}^*\right] = E\left[z_{it}\right].$$

Second, a solution to the program (47)-(50) has to satisfy, for all $k = 0, 1, 2, \dots$,

$$E\left[\left(\Delta_t - \hat{\Delta}_{it}^*\right) \hat{\Delta}_{it-k}^*\right] = 0.$$

Take a process $\{\hat{\Delta}'_{it}\}$ that does not have this property. Formally, for some $k \in \{0, 1, 2, \dots\}$,

$$E\left[\left(\Delta_t - \hat{\Delta}'_{it}\right) \hat{\Delta}'_{it-k}\right] \neq 0.$$

Then one can define a new process $\{\hat{\Delta}''_{it}\}$ as follows

$$\hat{\Delta}''_{it} = \left(1 + \alpha L^k\right) \hat{\Delta}'_{it},$$

where L is the lag operator and α is the projection coefficient in the linear projection of $\Delta_t - \hat{\Delta}'_{it}$ on $\hat{\Delta}'_{it-k}$. The new process has the property

$$\mathcal{I} \left(\{\Delta_t\}; \{\hat{\Delta}''_{it}\} \right) = \mathcal{I} \left(\{\Delta_t\}; \{\hat{\Delta}'_{it}\} \right),$$

because applying a one-sided linear filter to a stochastic process does not change the information flow. See proof of Lemma 2. Furthermore, the new process has the property

$$E \left[\left(\Delta_t - \hat{\Delta}''_{it} \right)^2 \right] < E \left[\left(\Delta_t - \hat{\Delta}'_{it} \right)^2 \right].$$

Thus the process $\{\hat{\Delta}'_{it}\}$ cannot be a solution to the program (47)-(50). It follows that a solution has to satisfy, for all $k = 0, 1, 2, \dots$,

$$E \left[\left(\Delta_t - \hat{\Delta}^*_{it} \right) \hat{\Delta}^*_{it-k} \right] = 0.$$

The same arguments yield that a solution has to satisfy, for all $k = 0, 1, 2, \dots$,

$$E \left[(z_{it} - \hat{z}^*_{it}) \hat{z}^*_{it-k} \right] = 0.$$

H Numerical solution procedure

Let the moving average representations for q_t and z_{it} be given by

$$q_t = \sum_{l=0}^{\infty} a_l \nu_{t-l},$$

$$z_{it} = \sum_{l=0}^{\infty} b_l \xi_{it-l},$$

where $\{\nu_t\}$ and $\{\xi_{it}\}$ are Gaussian white noise processes with unit variance. We make a guess concerning the stochastic process for the aggregate price level

$$p_t = \sum_{l=0}^{\infty} c_l \nu_{t-l}.$$

Applying Proposition 2, we solve the following constrained optimization problem

$$\min_{d,f,g,h} \left\{ E \left[\left(\Delta_t - \hat{\Delta}_{it} \right)^2 \right] + \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 E \left[(z_{it} - \hat{z}_{it})^2 \right] \right\},$$

subject to

$$\left\{ -\frac{1}{4\pi} \int_{-\pi}^{\pi} \log_2 [1 - \mathcal{C}_{\Delta, \hat{\Delta}_i}(\omega)] d\omega \right\} + \left\{ -\frac{1}{4\pi} \int_{-\pi}^{\pi} \log_2 [1 - \mathcal{C}_{z_i, \hat{z}_i}(\omega)] d\omega \right\} \leq \kappa,$$

with

$$\begin{aligned} \Delta_t &= \left(1 - \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|}\right) \sum_{l=0}^{\infty} c_l \nu_{t-l} + \frac{\hat{\pi}_{13}}{|\hat{\pi}_{11}|} \sum_{l=0}^{\infty} a_l \nu_{t-l}, \\ \hat{\Delta}_{it} &= \sum_{l=0}^{\infty} d_l \nu_{t-l} + \sum_{l=0}^{\infty} f_l \eta_{it-l}, \\ \hat{z}_{it} &= \sum_{l=0}^{\infty} g_l \xi_{it-l} + \sum_{l=0}^{\infty} h_l \zeta_{it-l}, \end{aligned}$$

where $\{\eta_{it}\}$ and $\{\zeta_{it}\}$ are Gaussian white noise processes with unit variance that are mutually independent and independent of $\{\nu_t\}$ and $\{\xi_{it}\}$. Here we make use of equation (63) to express information flow as a function of coherence.

Consider, as an example, the choice of the g_l and h_l , for all $l = 0, 1, \dots$. The following simplifications are helpful. Observe that in the objective

$$\left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}}\right)^2 E [(z_{it} - \hat{z}_{it})^2] = \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}}\right)^2 \left[\sum_{l=0}^{\infty} (b_l - g_l)^2 + \sum_{l=0}^{\infty} h_l^2 \right],$$

and in the constraint

$$\mathcal{C}_{z_i, \hat{z}_i}(\omega) = \frac{\left[\frac{G(e^{-i\omega})G(e^{i\omega})}{H(e^{-i\omega})H(e^{i\omega})} \right]}{\left[\frac{G(e^{-i\omega})G(e^{i\omega})}{H(e^{-i\omega})H(e^{i\omega})} \right] + 1},$$

where the polynomials $G(e^{i\omega})$ and $H(e^{i\omega})$ are defined as $G(e^{i\omega}) \equiv g_0 + g_1 e^{i\omega} + g_2 e^{i2\omega} + \dots$ and $H(e^{i\omega}) \equiv h_0 + h_1 e^{i\omega} + h_2 e^{i2\omega} + \dots$. The first-order condition with respect to g_l for any l is

$$\left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}}\right)^2 2(b_l - g_l) = -\frac{\mu}{4\pi \ln(2)} \int_{-\pi}^{\pi} \frac{\partial \ln [1 - \mathcal{C}_{z_i, \hat{z}_i}(\omega)]}{\partial g_l} d\omega,$$

where μ is the Lagrange multiplier. The first-order condition with respect to h_l for any l is

$$\left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}}\right)^2 2h_l = \frac{\mu}{4\pi \ln(2)} \int_{-\pi}^{\pi} \frac{\partial \ln [1 - \mathcal{C}_{z_i, \hat{z}_i}(\omega)]}{\partial h_l} d\omega.$$

We obtain a system of nonlinear equations in d, f, g, h and μ that we solve numerically.

Table 1: Parameters and main results for the benchmark economy

Parameters	Interpretation
$(\hat{\pi}_{13}/ \hat{\pi}_{11}) = 0.15$ $(\hat{\pi}_{14}/ \hat{\pi}_{11}) = 1$ $q_t = \sum_{l=0}^{20} a_l \nu_{t-l}, \nu_t \sim N(0, 1),$ with $a_0 = 1, a_l = a_{l-1} - 0.05, l = 1, \dots, 20$ $z_{it} = \sum_{l=0}^{20} b_l \xi_{it-l}, \xi_{it} \sim N(0, 1),$ with $b_0 = 10, b_l = b_{l-1} - 0.5, l = 1, \dots, 20$ $\kappa = 3$	Determines the sensitivity of prices to real aggregate demand y_t Determines the sensitivity of prices to the idiosyncratic state variable z_{it} The MA representation of nominal aggregate demand q_t The MA representation of the idiosyncratic state variable z_{it} The upper bound on the information flow
Main results	Interpretation
8.2% $\kappa_1^* = 0.19, \kappa_2^* = 2.81$ $E \left[\left(\Delta_t - \hat{\Delta}_{it}^* \right)^2 \right] = 0.39$ $\left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 E \left[\left(z_{it} - \hat{z}_{it}^* \right)^2 \right] = 2.1$	The average absolute size of price changes per period 94% of attention allocated to the idiosyncratic state Expected loss from imperfect tracking of Δ_t Expected loss from imperfect tracking of z_{it}

Table 2: Varying parameter values

Changes in parameter values relative to the benchmark economy in Table 1	Changes in results
$a_0 = 50, a_l = a_{l-1} - 2.5, l = 1, \dots, 20$ Larger variance of nominal aggregate demand	The average absolute size of price changes per period is 35% κ_1^* increases to 76% of κ $E \left[\left(\Delta_t - \hat{\Delta}_{it}^* \right)^2 \right] = 75.6, \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 E \left[\left(z_{it} - \hat{z}_{it}^* \right)^2 \right] = 54$
$b_0 = 12, b_l = b_{l-1} - 0.6, l = 1, \dots, 20$ Larger variance of the idiosyncratic state variable	The average absolute size of price changes per period is 10% κ_1^* decreases to 4% of κ $E \left[\left(\Delta_t - \hat{\Delta}_{it}^* \right)^2 \right] = 0.44, \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 E \left[\left(z_{it} - \hat{z}_{it}^* \right)^2 \right] = 2.7$
$(\hat{\pi}_{13} / \hat{\pi}_{11}) = 0.1$ More strategic complementarity in price setting	The average absolute size of price changes per period is 8.2% κ_1^* decreases to 5% of κ $E \left[\left(\Delta_t - \hat{\Delta}_{it}^* \right)^2 \right] = 0.31, \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 E \left[\left(z_{it} - \hat{z}_{it}^* \right)^2 \right] = 1.9$
$(\hat{\pi}_{13} / \hat{\pi}_{11}) = 0.3$ Less strategic complementarity in price setting	The average absolute size of price changes per period is 8.2% κ_1^* increases to 9% of κ $E \left[\left(\Delta_t - \hat{\Delta}_{it}^* \right)^2 \right] = 0.62, \left(\frac{\hat{\pi}_{14}}{\hat{\pi}_{11}} \right)^2 E \left[\left(z_{it} - \hat{z}_{it}^* \right)^2 \right] = 2.3$
